INTRODUCTION

The functional anatomy of the elbow joint complex is unique in orientation and configuration. The elbow is the mechanical junction between the first two segments of the upper limb, and its main function is to move the hand away from and bring it closer to the trunk [1]. To perform these actions, this joint must be mobile, stable, and mostly painless. The head of the radius is a secondary stabilizer of the elbow according to Morrey's tripod [2]. It contributes to the overall stability of the elbow and the transmission of stresses, whatever the degree of extension flexion [3]. Its role in frontal and rotational stability has been highlighted by several authors [2,4,5]. Fractures of the head of the radius represent 1.5% to 4% of all fractures and 33% of all bone lesions in the elbow [6]. In these fractures, internal fixation of types 3 and 4 of the Masson classification, modified by Broberg and Morrey [7], is difficult and may not be possible in some cases [7,8]. The choice between resection of the radial head or arthroplasty is dependent on the associated ligament lesions, the equipment available, and the technical skills of the surgical teams. This study aimed to assess the function of the elbow after resection of the radial head in adults.
RESULTS

At an average follow-up of 47.6 months, of the 11 patients reassessed, two had mild mechanical pain. Six patients had a functional arc greater than 100°, and this arc varied from 50° to 100° in the other 5. In regard to elbow mobility (Table 1), the average degree of flexion was 97.73° ± 16.03° and the average deficit of extension was 23.6°. The mean pronation and supination values were 76.8° and 74.5°, respectively. Overall, a cubitus valgus with an average value of 12.8° ± 4° was identified. Instability as assessed by forced valgus movements was present at a moderate degree in two of 11 cases and was absent in the other nine. A cumulative total of 21 complications was found in all patients. In eight cases, the issue was a limitation of the range of motion, seven cases had elbow valgization (Fig. 1), two cases had instability in the valgus (Figs. 2 and 3), and four cases had heterotopic ossifications (Figs. 4 and 5). No complications such as radial head ascension or Essex-Lopresti syndrome were noted. There were no daily activity limitations in 10 cases. Seven patients continued their professional activities, three had to adjust their original jobs, and one patient had not yet returned to work. The average score for all patients was 83.2 ± 11 points out of 100, and 81% were graded as good according to the MEPI. Elbow function was excellent in three cases, good in six cases, and average in two cases (Fig. 6).

DISCUSSION

Resection of the radial head is a therapeutic indication of interest, and several authors have reported similar findings in the literature. Characteristics of average age, male predominance, and impairment of the dominant side were reported by Karlsson et al. [9] and Obert et al. [10]. Work accidents have been implicated in most studies as the main cause of injuries [10]. Type 3 and 4 fractures according to the Mason classification were the most com-

The time from initial injury to operation varied from 8 days on average in the study by Eren et al. [11] to 29 days in the report from Obert et al. [10]. Our average follow-up of 4 years was still quite short compared to other studies. The longest follow-up period observed was 19 years in the Karlsson et al. [9] study and 30 years in the Janssen and Vegter [12] study. Radial head resection surgery has associated complications that can interfere with elbow function. Ascension of the head and instability in the valgus are complications specific to this indication and are frequently accompanied by valgization of the elbow [12-14]. Other complications common to any joint surgery such as joint limitations and heterotopic ossifications are quite common [15]. These specific and non-specific complications are often responsible for stiffness that further affects the function of the elbow [16]. In this study, valgization of the elbow was found in 63.6% of the cases compared to 20% in the Karlsson et al. [9] study. However, there was slight valgus instability that was identified in only 18% (2/11) of cases. This valgisation of the elbow had no impact on function. Antuna et al. [17] reported instability in the valgus at around 19%, similar to our study. Similar to the reports from Karlsson et al. [9] and Antuna et al. [17], rise of the radial head was not reported in our series. Heterotopic ossifications were found in 36% of our cases compared to 62% in the study by Obert et al. [10] with an average follow-up of 16 years. These ossifications were usually found around the resection edge in cases that did not have the space filled after radial head resection. However, these results did not impair the range of motion of the elbow. Joint limitation occurred in five (45.4%) of 11 patients. The range of joint limitation in these patients was between 50° and 100°. The proportion of this complication is three times higher than that reported by Eren et al. [11]. This can be explained by the relatively long term of immobilization in our series, which was an average of 30 ± 6 days. Long-term immobilization has been identified as a source of stiffness [18,19]. Active mobilization immediately after removal of the radial head is currently recommended because it induces formation of a functional cervico-condylar neoarticulation [20]. Regarding elbow mobility, almost all sectors had results similar to those found in the literature, with the exception of flexion. The average value for flexion was quite low, and the difference ranged from 30° to 40°, compared to results from Eren et al. [11], Karlsson et al. [9] and Antuna et al. [17]. This can be explained by the late start of mobilization or the osteoligamentary lesions in our series, dislocations in 45.4% of the cases (five cases of 11) and a terrible triad in three cases. In addition, the other studies had a longer rehabilitation period than ours, which may improve final results. Therefore, the functional score of the MEPI in our study was quite low, on aver-

age 10 points lower than those of similar studies. However, this score of 83.2 points out of 100 ranked the patients in our series at an overall function level of 81%. This level of function is judged to be good according to this assessment tool whose precision and reliability are internationally recognized [21]. The majority of patients was able to resume their professional activities without difficulty. This study had some limitations. First, due to the limited amount of follow-up and relatively small number of patients, the results cannot be generalized to a larger population. On the other hand, a relatively short-term follow-up in the revaluation did not allow us an overview of the long-term functionality. Finally, that the patients were operated on by several surgeons, and that some had additional osteoligamentary lesions, may have produced selection bias.

Despite the fairly limited size of this series, resection of the radial head for a fracture that cannot be operated on by internal fixation was associated with rather satisfactory results, with moderate loss of mobility. Notwithstanding mild clinical signs of instability, residual elbow pain and disability were mild. These results suggest that radial head resection remains a useful surgical procedure for irreparable radial head fractures.
