INTRODUCTION

Acromial spurs are a common finding in patients with shoulder pain and are known to be an extrinsic factor that can trigger rotator cuff disorders [1]. The presence of an acromial spur implies the existence of a rotator cuff disorder due to impingement between the acromial spur and the rotator cuff. Numerous studies have reported a relationship between acromial spurs and rotator cuff disorders, and larger acromial spurs are reported to be an important defining factor in success with the diagnosis and treatment of rotator cuff tears in patients with shoulder pain [1-3].

Acromial spurs are usually detected on plain radiographs. Bigliani et al. [1] classified the acromion, based on the shape of its undersurface on supraspinatus outlet-view radiographs, as follows: type I (flat), type II (curved), and type III (hooked). Type III acromion is strongly associated with rotator cuff tears. Kitchel [4] subsequently introduced the 30° caudal-tilt view to evaluate the anterior acromion. Later, Ono et al. [5] reported a close correlation between arthroscopic findings for acromial spur and those obtained using the 30° caudal-tilt view.
Due to its noninvasiveness and cost-effectiveness, ultrasonography is a useful diagnostic method for patients with shoulder pathology [6,7]. Ultrasonography can be used to obtain multiplanar images of fractures around the shoulder joint, while plain radiography only provides a two-dimensional view of the area of interest. Fractures of the coracoid process, greater tuberosity, and scapula are readily detected by ultrasonography, whereas they occasionally go undetected on plain radiographs [8,9]. Acromial spur, by its osseous nature, can also be easily detected using ultrasonography. By offering real-time images and the ability to recreate a shoulder-impingement condition, ultrasonography can provide meaningful clinical information regarding the relationship between the acromial spur and symptoms. However, to our knowledge, no study has yet diagnosed or measured acromial spurs using ultrasonography.

The purpose of the study was therefore to observe acromial spurs using ultrasonography and to compare measurements thereof between plain radiographs and sonograms. A close correspondence between plain radiography and ultrasonography spur measurements was expected. The hypotheses of our study were that the anteriorly projected acromial spurs would be well-visualized by ultrasonography and the lengths of the spur as measured using ultrasonography and plain radiography, respectively, would be comparable.

**METHODS**

This study protocol was approved by the Institutional Review Board of Eunpyeong St. Mary’s Hospital, which waived the requirement for informed consent due to the retrospective nature of the study.

**Patient Enrollment**

Routine preoperative ultrasonography data from 95 patients who underwent arthroscopic acromioplasty with rotator cuff repair were retrospectively reviewed. Among these 95 patients, only those patients documented to have confirmed acromial spur on both ultrasonography and plain radiography were enrolled, resulting in a total of 51 consecutive study participants. Patients with fractures, infections, tumors, or labral disorders, including instability, were excluded. All surgeries were performed at a single university hospital by a senior shoulder surgeon.

**Radiological Assessment of the Acromial Spur**

The acromial spur was analyzed in both the supraspinatus outlet view and the 30° caudal-tilt view on plain radiographs. The length from the anterior acromion to the most projected point of the acromial spur was measured in the supraspinatus outlet view and 30° caudal-tilt view. All measurements were performed by two orthopedic surgeons (HSS and HK) and were made with a picture archiving and communication system (Marosis M-view ver. 5.4; Marotech, Seoul, Korea) (Fig. 1).

**Ultrasonography Assessment of the Acromial Spur**

Preoperative ultrasonography was performed and real-time images were obtained with a linear 1- to 15-MHz transducer (Philips HD11 XE; Philips Medical Systems, Andover, MA, USA). All ultrasonography examinations were performed by the same senior shoulder surgeon (HSS), with the patient sitting on a chair and the examiner standing behind the patient. During the assessment, the patient’s shoulder was positioned in a neutral position, with the elbow flexed and hand supinated, to allow examination of the acromial spur. The transducer was held vertically and continuously moved laterally to medially, which corresponded to a range from the long axis of the long head of the biceps to the short axis of the subscapularis (Fig. 2). The ultrasonography images were saved as videos for analysis. Still images were obtained when the acromial spur was most...
visible in the ultrasonography videos and the distance from the anterior margin of the acromion to the most distal point of the acromial spur was measured on said still images (Fig. 1C). All measurements were performed by two orthopedic surgeons (HSS and HK), who were blinded to the diagnosis and interpreted the measurements independently of one another.

Statistical Analysis
Repeated-measures analysis of variance was used to compare the supraspinatus outlet view, 30° caudal-tilt view, and ultrasonography measurements of the distance from the anterior margin of the acromion to the most distal point of the acromial spur. The paired t-test was used to compare the measured distances between the supraspinatus outlet view and the 30° caudal-tilt view, the supraspinatus outlet view and sonogram, and the 30° caudal-tilt view and sonogram, respectively. A simple correlation analysis was used also performed to compare the collected measurements between the imaging modalities. IBM SPSS ver. 24.0 (IBM Corp., Armonk, NY, USA) was used for all statistical analyses. Significance levels for all analyses were set at p < 0.05.

RESULTS

Patient Demographics
The mean age of the patients was 60.6 years (range, 36–78 years) and 29 of 51 patients were women (56.9%). The dominant shoulder was affected in 42 cases (82.4%). One patient who underwent bilateral surgery was also enrolled, so 52 cases were included in the final analysis.

All patients had at least one pathology in the supraspinatus, subscapularis, and/or long head of the biceps. In total, 48 patients (92.3%) had pathologies in the supraspinatus tendon, including 35 (67.3%) with full-thickness tears and 13 (25%) with partial-thickness tears. Meanwhile, there were 28 patients (53.8%) with pathologies in the subscapularis tendon, including one (1.9%) with a full-thickness tear and 27 (51.9%) with partial-thickness tears. Finally, 28 patients (53.8%) had pathologies in the biceps long head tendon, including six (11.5%) with total tendon rupture and 22 (42.3%) with partial tendon rupture.

Comparison of Measurements
The mean acromial spur length, as measured in the supraspinatus outlet view, was 4.2 ± 3.7 mm, while that in the 30° caudal-tilt view was 4.8 ± 3.9 mm. No significant difference was found between the plain radiograph (supraspinatus outlet view and 30° caudal-tilt view) and ultrasonography measurements (p = 0.186); however, a significant difference was found between the two plain radiographs (p = 0.008). Meanwhile, no significant difference was found between the ultrasonography and supraspinatus outlet-view measurements (p = 0.363) or between the ultrasonography and 30° caudal-tilt view measurements (p = 0.451).

A strong correlation was detected between the supraspinatus outlet view and 30° caudal-tilt view measurements (r = 0.922, p = 0.000), while a moderate to strong correlation was observed between the ultrasonography and supraspinatus outlet-view measurements (r = 0.776, p = 0.000) and between the ultrasonography and 30° caudal-tilt view measurements (r = 0.734, p = 0.000). A scattered plot of the plain radiograph and ultrasonography measurements is shown in Fig. 3.

DISCUSSION

In this study, no significant difference was found in the length of the acromial spur when using plain radiography (supraspinatus outlet view and 30° caudal-tilt view) versus ultrasonography. Moreover, a strong correlation was observed between the plain radiography and ultrasonography measurements.

The morphology of the acromion attracted attention following the introduction of impingement theory for rotator cuff tear by Neer [10]. Bigliani et al. [1] classified the acromion by shape and many subsequent studies have since reported that their type III acromion is associated with rotator cuff tears [11,12]. However, the reliability of the classification system by Bigliani et al. [1] remains controversial due to low interobserver reliability and the relatively poor image quality of plain radiographs [13,14].

An acromial spur forms due to traction of the coracoacromial ligament. Although the etiology of rotator cuff tears is unclear, acromial spurs are convincing as a causative factor. Several imaging studies and cadaveric studies have reported acromial spur as a degenerative change that can lead to tearing of the rotator cuff [15–17]. Ogawa et al. [2] classified acromial spurs by length, as measured in the supraspinatus outlet view, and reported that spurs measuring more than 5 mm have diagnostic value for the...
occurrence of rotator cuff tear. Tucker and Snyder [3] introduced the concept of keel spurs, which resemble a sailboat keel; such spurs may be observed on the undersurface of the acromion on plain radiographs. Further, they theorized that patients with a keel spur are at significant risk of bursal sided partial-thickness and full-thickness rotator cuff tears. For such reasons, acromioplasty is commonly performed during rotator cuff repair and also as a part of subacromial bursectomy [18]. Ono et al. [5] used the 30° caudal-tilt view to evaluate an anteriorly prominent acromial spur. Inferiorly projecting spurs can be visualized more easily by tilting the X-ray beam 30° superior to inferior. Both the supraspinatus outlet view and 30° caudal-tilt view were adopted in this study.

Fig. 3. Scattered plot showing a moderate correlation between plain radiography and ultrasonography measurements. (A) Supraspinatus outlet view and 30° caudal-tilt view. (B) Supraspinatus outlet view and ultrasonography. (C) Thirty-degree caudal-tilt view and ultrasonography.

As imaging modalities and arthroscopic techniques have progressed, acromial spurs can now be classified based on computed tomography (CT), magnetic resonance image (MRI), and arthroscopic findings. Oh et al. [19] classified acromial spurs based on their shape and thickness revealed by plain radiography and MRI arthrography or CT arthrography. In their study, acromial spurs were classified into six types. The heel spur was the most common type in their rotator cuff tear group; the mean acromial thickness in their cohort was 8.0 mm, but was thicker in the rotator cuff tear group. Kongmalai et al. [20] classified acromial spurs based on 30° caudal-tilt view and arthroscopic findings, where keel spur was the most common finding, followed by heel spur. These authors [20] described patients with either of these spur types as “being at-risk” of a supraspinatus tendon tear. In our study, laterally protruding or medial-type spurs on the short axis of the subscapularis or long axis of the long head of the biceps were not analyzed by ultrasonography. However, anteriorly projected spurs, which are suggested to be a risk factor for rotator cuff tears, were observed and measured on sonograms and plain
radiographs.

Ultrasoundography is suitable for detecting and diagnosing soft tissue disorders, including rotator cuff tears [21-23]. Moreover, the ready accessibility and dynamic imaging of ultrasonography render it suitable for diagnosing calcific tendinitis and fractures [24,25]. Calcium deposits appear hyperechoic with or without posterior acoustic shadowing, while fractures appear as an interruption of the smooth cortical surface. Ultrasoundography is commonly used to guide injections and more invasive procedures, such as needling and barbotage for treating calcific tendinitis [26,27]. In this study, it was seldom difficult to distinguish between acromial spurs and the coracoacromial ligament. Since ultrasoundography provides dynamic images, the study participants were asked to extend or rotate their arm internally or externally. Acromial spurs remained still during movement of the humeral head, different from the coracoacromial ligament, which experienced some movement. This discrepancy helped to differentiate acromial spurs from the coracoacromial ligament. Also, multiplanar images, which ultrasoundography provides, helped to identify the shape of the spur and to measure the length.

This study had some limitations. First, there was a degree of measurement bias associated with the picture archiving and communication system, although the mean values of two blinded interpreters were obtained to overcome this. Second, measurement bias also arose from beam projection and magnification errors on the plain radiographs. Third, acromion type—and anatomical variations therein—were not assessed. Fourth, only anteriorly projected spurs were observed on ultrasonography; medial and inferior spurs are difficult to observe using ultrasonography. Fifth, there is a possibility of selection bias as this study was a retrospective investigation and included a relatively small population sample (52 cases). However, all of the ultrasonography examinations were performed by a single surgeon with 10 years of ultrasound experience and a case volume of 100 cases per month.

Some strengths of this study should also be discussed. First, this is the first study to our knowledge to measure acromial spurs using ultrasonography. This study revealed a correlation between plain radiography and ultrasonography findings. The results suggest that ultrasonography has diagnostic value for confirming rotator cuff disorders having an acromial spur.

Anteriorly projected acromial spurs were well-visualized by ultrasonography. No differences in acromial spur length were detected between on plain radiographs (supraspinatus outlet view and 30° caudal-tilt view) and sonograms. The correlation coefficients between the plain radiographs and ultrasonography measurements exceeded 0.7.
