Irreparable massive rotator cuff tears cause pain, loss of function, and a decrease in range of motion, which cause serious disturbances in daily life. Young patients, in particular, are active and have relatively high functional requirements, and their surgical options are limited. Superior capsular reconstruction (SCR) was first proposed for irreparable massive rotator cuff tears, good clinical results have been reported in short-term follow up. Since then, SCR has been used increasingly worldwide for irreparable massive rotator cuff tears, and various studies have been published on clinical outcomes, biomechanical outcomes, surgical techniques, and graft types. This article reviews the optimal graft and surgical options for improving clinical outcomes in SCR.

Keywords: Rotator cuff; Shoulder; Superior capsular reconstruction; Tendon

INTRODUCTION

Irreparable massive rotator cuff tears cause pain, loss of function, and a decrease in range of motion, which cause serious disturbances in daily life [1,2]. In addition, since repairing irreparable massive rotator cuff tears have difficulty in complete footprint coverage and a high frequency of re-rupture, the postoperative clinical results often are unsatisfactory [3,4]. For this reason, in elderly patients with relatively few functional requirements, there are various surgical options for massive rotator cuff tears, such as debridement, biceps tenotomy/tenodesis, partial repair, tendon transfer, and reverse total shoulder arthroplasty (RTSA) [5-7]. However, since young patients are active and have relatively high functional requirements, these surgical options are limited to tendon transfer and patch augmentation [8,9]. In addition, although previous studies have reported that RTSA has good clinical result in elderly patients with massive rotator cuff tears, RTSA in active young patients under the age of 65 demonstrates relatively high complications and failure rates, and it is not an optimal surgical option in terms of longevity [10-12].

Mihata et al. [13, 14] first proposed superior capsular reconstruction (SCR) using autologous tissue for irreparable massive rotator cuff tears, and they reported good clinical results in short-term follow up. Since then, SCR has been increasingly used for irreparable massive rotator cuff tears, and they reported good clinical results in short-term follow up. Since then, SCR has been increasingly used for irreparable massive rotator cuff tears, and various studies have been published on clinical outcomes, biomechanical outcomes, surgical techniques, and graft types. A previous systematic review reported that SCR reduced acromial contact pressure, produced superior humeral translation, and improved short-term clinical outcomes [15,16]. However, biologic healing at the contact surface between graft and bone is the most important factor to improve mid- and long-term outcomes of SCR [16,17]. Therefore,
for optimal biologic healing, selection of an optimal graft and appropriate surgical technique must be considered. For this reason, this article reviews the optimal graft and surgical options for improving clinical outcomes in SCR.

**GRAFT OPTIONS**

Mihata et al. [13] originally used a fascia lata autograft to reconstruct the superior capsule. Although their early results are promising, the fascia lata graft is thin, requiring doubling of the construct and a relatively large donor incision for harvesting. As an alternative, acellular dermal allografts were proposed for their theoretical advantages of reduced donor site morbidity, shorter associated operative times, ease of preparation, and strength of the graft [18,19]. Most of the previously reported studies described SCR using fascia lata graft or dermal allograft (Table 1) [20-29]. Various biomechanical studies and clinical results report their use in SCR. Recently, however, various other autografts, allografts, xenografts, and synthetic grafts have been used in SCR, and the clinical results have been reported (Table 2) [30-34].

**Tensor Fascia vs. Dermal Allograft**

In a biomechanical cadaveric study comparing a fascia lata graft and a human dermal graft, single-layered human dermal allografts partially restored superior glenohumeral stability, whereas a fascia lata allograft completely restored superior glenohumeral stability [35]. A biomechanical comparison on the effect of SCR using a 3- and 6-mm-thick acellular dermal allograft demonstrated that SCR with a 6-mm-thick acellular dermal allograft better restored normal glenohumeral joint position and forces compared with a 3-mm-thick graft [36]. A biomechanical characterization of SCR using a fascia lata allograft, double layer dermal allograft, and single layer dermal allograft revealed that all three graft types can restore superior translation and subacromial contact pressure depending on the glenohumeral abduction angle, and fascia lata and double layer dermis can be more effective than single layer dermis [37]. SCR with a single 6-mm-thick acellular dermal allograft is non-inferior to fascia lata regarding subacromial space distance and peak subacromial contact pressures while restoring the superior stability of the glenohumeral joint compared to an intact joint [38].

Mihata et al. [39] reported the functional and radiographic results of SCR after 5 years of follow-up. Healed arthroscopic superior capsule reconstruction restored shoulder function and resulted in high rates of return to recreational sport and work. None of the 27 patients who experienced graft healing showed progression of cuff tear arthropathy, but all three patients with a graft tear had severe cuff tear arthropathy at 5 years postoperatively. A systematic review described two studies using only a fascia lata autograft and three studies using only a human dermal allograft, and the mean follow-up time ranged from 12 to 48 months. All studies reported statistically significant and clinically important mean improvements in active elevation (range of means, 28°–56°), the Constant score (range of means, 12–47.1 points), or the American Shoulder and Elbow Surgeons (ASES) score (range of mean, 29.3–56 points). In total, 218 shoulders underwent postoperative magnetic resonance imaging. The graft tear rate reported in the studies using a fascia lata autograft (181 shoulders) ranged from 5% to 32%, whereas the values reported in studies using a human dermal allograft (37 shoulders) ranged from 20% to 75% [40]. Another systematic review reported five fascia lata autograft clinical studies and four only-human dermal allograft clinical studies. Increases in ASES scores, forward elevation and external rotation values, and acromiohumeral distance (AHD) were found in all clinical fascia lata autograft studies. The human dermal allograft clinical studies reported increases in ASES scores, forward elevation values, and AHD but decreases in VAS scores [16].

**Other Graft Materials**

In SCR, there are not many studies on grafts other than fascia lata and dermal graft. However, as with patch augmentation in massive rotator cuff tears, various types of grafts are being tried. Few reports on the clinical outcome of these various grafts exist, and the surgical techniques are still mostly introduced.

**Biceps autograft**

The long head of the biceps tendon (LHBT) is a local autograft; the patient does not have donor site morbidity. All procedures are performed on the same shoulder, reducing operative time and risk of infection. Preserved vascular supply of the transposed LHBT can improve healing progression of rotator cuff repair. There is no extra cost for an allograft or an artificial graft [31]. Few reports reveal the clinical outcome of SCR using LHBT, but it has been reported to have significant effects in several biomechanical studies [41,42]. Most reports describe the surgical technique of SCR using LHBT [31,43-46].

El-Shaa et al. [42] reported in a study of 10 cadaveric shoulders that SCR with an LHBT autograft is a feasible procedure that is biomechanically equivalent and potentially even stronger than SCR with a fascia lata autograft for prevention of superior humeral migration. SCR with an LHBT autograft required 393.2% ± 87.9% (p = 0.029) of the force needed for superior humeral migration in massive rotator cuff tear, while SCR with a

fascia lata autograft required 194.00 ± 21.8% (p = 0.013). The LHBT reconstruction group trended toward a stronger reconstruction when normalized to the torn condition (p = 0.059). Han et al. [41] reported a cadaveric study in seven shoulders. A modified SCR using LHBT both with and without side-to-side repair shifted the humeral head inferiorly at 30° and 60° of glenohumeral abduction, with the contact area further reduced at 60°. The techniques had comparable results for contact pressure and total rotational range of motion. They suggested that the LHBT with appropriate distal insertion on the greater tuberosity restores shoulder stability in irreparable rotator cuff tears by re-centering the humeral head on the glenoid.

Barth et al. [30] reported the clinical outcomes in 24 patients who underwent SCR with LHBT autograft. Twenty-four months after surgery, the group undergoing SCR with the LHBT showed improvement in absolute Constant score from 50 to 77, ASES from 45 to 80, Subjective Shoulder Score from 41% to 75%, the Simple Shoulder Test from 3.6 to 8.4, and the visual analog scale (VAS) from 5.2 to 1.4. In all cases, the p-value was < 0.001. The strength of the operated arm improved from 2.3 kg to 6.4 kg (p < 0.001), and 91.7% (22/24) of the SCR group remained healed on ultrasound.

**Semitendinosus tendon autograft**

Rosales-Varo et al. [47] proposed an open technique for SCR with an autologous semitendinosus tendon graft in a reverse V-shaped configuration (single fixation point on the glenoid and double fixation on the greater tuberosity). They found an improvement in Constant score from 49 (before SCR) to 77.25 (1 year after the operation). The mean active flexion significantly increased from 99.3° to 142.5° (p < 0.01). The mean preoperative AHD increased from 5.25 (before surgery) to 8.18 (after SCR). There were no tears of the graft during follow-up [47]. The technique is safe and reliable and has some potential advantages related to cost and lesser morbidity than the fascia lata autograft. Moreover, the tendon length allows for different configurations (double strand, V shaped, reverse V shaped, or box shaped). Mi-
Xenograft

Acellular porcine dermal xenograft

Polacek [50] evaluated the short-term clinical outcomes and complications related to arthroscopic SCR with an acellular porcine dermal xenograft for treatment of irreparable massive rotator cuff tears in a total of 20 shoulders in 19 patients with rotator cuff tear. He reported mean range of motion, and the Shoulder Pain and Disability Index score showed significant improvement from 51.3% to 10.4% at 1-year follow-up. However, the procedure had a 30% complication rate, including a 15% rate of immunologic rejection of the xenograft [50].

DX reinforcement matrix

Kalina et al. [32] reported the clinical outcome of SCR using the DX Reinforcement (Arthrex, Naples, FL, USA) at 1 year (range, 6–18 months) in a total of 20 SCRs. The University of California–Los Angeles score improved from 10 to 29, the ASES from 23.8 to 73.2, and the VAS from 7 to 2. The mean active shoulder flexion was 74° preoperatively and 161° postoperatively. The mean active abduction was 74° preoperatively and 161° postoperatively. The mean active external rotation of the shoulder joint was 20° preoperatively and 56° postoperatively. The mean active external rotation at 90° abduction was 21° preoperatively and 82° postoperatively. No complication specifically associated with use of xenograft has been reported.

Teflon patch

Teflon felt has been used for conventional patch graft surgery [51-53] (tendon reconstruction for rotator cuff tears), as well as in thoracic and cardiovascular surgery [54]. Okamura et al. [34] investigated the clinical and radiographic outcomes and postoperative complications of SCR using a Teflon graft of either 1 or 3 layers. They reported that SCR using a Teflon graft of either 1 or 3 layers significantly improved the ASES and VAS scores and muscle strength in shoulder abduction, with low rates of graft tears and complications after surgery.

GRAFT THICKNESS AND SIZE

In a previous cadaveric study, the thickness of the superior capsule of the normal glenohumeral joint was reported from 4.1 mm to 9.1 mm [55]. Biomechanically, although both 4-mm- and 8-mm-thick fascia lata allografts reduced subacromial peak pressure after SCR, only the thicker 8-mm graft was able to decrease superior translation [56]. In an acellular dermal allograft, using a 6-mm-thick graft demonstrated similar maximum abduction angle, glenohumeral superior translation, subacromial peak contact pressure, and cumulative deltoid force compared with the intact state. When comparing the 3-mm- to the 6-mm-thick graft, significant differences were found in glenohumeral superior translation [36]. When comparing the 6-mm-thick acellular dermal allograft and the 8-mm-thick fascia lata allograft, SCR with a single, 6-mm-thick, acellular dermal allograft is non-inferior to a fascia lata tendon regarding subacromial space distance and peak subacromial contact pressures while restoring the superior stability of the glenohumeral joint compared to the intact state [38]. These results reveal that graft thickness determines the degrees of superior migration through compression of the humeral head. So, to visualize this effect adequately, graft thickness should be at least 6 mm in SCR.

GRAFT TENSIONING (FIXATION ANGLE)

For optimal fixation, graft tensioning has been implicated to play a major role in glenohumeral contact properties and forces [56]. In addition, previous literature suggests differences in ideal abduction angles during SCR graft fixation based on type of material used intraoperatively [20,56]. One method for tensioning the graft is through abduction of the glenohumeral joint during fixation. Mihata et al. [56] suggested that 8 mm graft thickness and an arm position between 15° and 45° of shoulder abduction are the major aspects for sufficient reconstruction of the superior capsule. Various abduction angles using dermal allografts have been described, ranging from 20° to 45° of clinical shoulder abduction [18,57]. However, the optimum graft tension for best results in SCR remains unclear. Adams et al. [58] reported that SCR with anterior and posterior margin convergence tensioned at 15° of glenohumeral abduction showed similar deltoid abduction force requirements to the native state in their biomechanical study. Dyrna et al. [59] reported in a biomechanical study of 10 fresh-frozen cadaveric shoulders that SCR using a graft fixed under tension (30 to 35 N) demonstrated a significant increase in maximum shoulder abduction compared with a nontensioned graft (65.0° ± 12.6° vs. 54.1° ± 16.1°, p = 0.04). However, abduction remained significantly less than in the intact state (79.8° ± 5.8°, p = 0.04). A tensioned SCR restored a maximum abduction of 81% of the native condition. Clinically, most surgeons have performed SCR graft fixation at 10° to 45° shoulder abduction per Mihata’s recommendation [21-24]. But, there is a lack of clear clinical evidence for optimal abduction angle based on graft type in SCR.
MARGIN CONVERGENCE SUTURING (SIDE-TO-SIDE SUTURING)

Mihata et al. [13] recommended side-to-side suturing between the graft and infraspinatus tendon or subscapularis tendon when performing SCR in irreparable rotator cuff tears. In biomechanical studies, SCR without side-to-side suturing did not decrease glenohumeral superior translation, although subacromial peak contact pressure decreased [60]. Adding side-to-side suturing restored superior stability to the intact level by achieving capsular continuity in the transverse direction. Total ROM did not decrease significantly after SCR with or without side-to-side suturing when the graft size matched the defect size [60].

ACROMIOPLASTY

Although SCR can increase the AHD, friction can be induced on the undersurface of the graft and acromion through movement after surgery, and this can cause a tear in the graft. Mihata et al. [13] recommended acromioplasty during SCR for irreparable rotator cuff tears. They also investigated the effects of acromioplasty on shoulder biomechanics after superior capsule reconstruction for irreparable supraspinatus tendon tears [61]. Including acromioplasty decreased the subacromial contact area without increasing the subacromial contact pressure in SCR. Clinically, it is not necessary to perform acromioplasty in SCR, and acromioplasty was not necessarily performed in other studies. However, most surgeons performed acromioplasty if there was evidence of abrasion on the undersurface of the acromion [24,62,63].

CONCLUSION

Since Mihata et al. [13] introduced SCR for irreparable rotator cuff tear several years ago, various studies on SCR have been conducted, and considerable progress has been made. The long-term clinical results of SCR are insufficient, however, and further studies on the various factors necessary for the best results in irreparable rotator cuff tear are needed. Knowledge of these various factors that must be considered for a successful SCR will lead to a better life for patients with massive rotator cuff tears.
